Final Report:

Using Patient Triage and Historical Data to Predict the disposition before seen by the provider

Problem statement:

According to CDC, the national number of Emergency Department visit is 130 million in year 2018. Out of those visits, there were about 12.4% (16.2 million) resulting in hospital admission. Many times, patients who has long ED length of stay were waiting the bed to be available in Hospital Inpatient units. To help the hospital providing adequate resources and shorten the ED Length of Stay for a patient, it will be very helpful if there is a way to predict hospital admissions right after Triage.

Can use machine learning to help predict hospital admission at the time of ED triage using patient history in addition to information collected at triage?

Data Wrangling:

The raw dataset from Woo Suk Hon, Adrian Daniel Haimovich and R.Andrw Tayor has 972 variables with total of 560,486 adult patients. Because it's a very huge dataset, so there is a need to do a little cleaning.

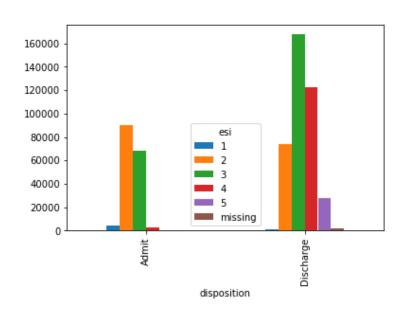

First, find out what are the columns with NaN data and the need to fill the NaN with propriate value. For Binary Type, fill 0 for all the missing values, For Categorical type, fill the missing according the the category, most are other or missing or refused.

I didn't delete any row, so the final shape of the dataset is still 972 columns with 560486 rows.

Exploratory Data Analysis:

To understand the data, I did counts to understand:

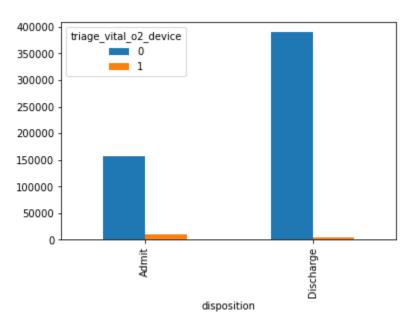

- how many patients were admitted and how many were Direct Discharge from ED.
- The counts for ESI, which is the Acuity Level
- Compare the number patients of different ESI from Admit to Discharge

The Graph shows that patients who were with ESI 1 and 2 were Admit from ED more then patient who where with ESI 4 and 5.

The majority of ESI 3 patients also direct discharge from the ED as well

- Compare the number of patient with O2_decive when entering ED from Admit to Discharge

Patient came in with O2 device did got admit to the hospital more.

The count of chief-complains when patient coming to ED and compare it's disposition

I can't list all the tables due to too many chief-complains, however, the take does show that some chief complains has higher number of patients been admit to hospital.

I also use describe function to understand the summary of Triage Only data for Admit patients and discharge patient. To see if there is large difference between the mean, std, and others. Also create a box plot to see the difference between each Triage Vital and it's disposition.

The median of triage vitals shows not much difference from Admit to Discharge. However, the range of the vital is larger in Admit patients.

Model Selection:

I split the date into three different datasets: Triage Data Only, Historical Data Only and the full dataset. I want to see if it will make difference and if we can reduce the variables to do the prediction.

I test two different machine learning classification models: Logistic Regression, GradientBoosting. The Metric I focused on is the Accuracy. I want my model to correctly predict the disposition.

Before building the models, I deleted few variables that I think wont have much impact, like religion, employstatus, insurance_status....etc. Due to the nature of the machine learning, I also can't leave any null values in the dataset, so I search the best to way to fill the null value with extreme values (-9999). According to the experts, the machine learning model will ignore the extreme values.

When it comes to the models, I use mostly the default value. However, in Logistic Regression, due to the data size, I need to set a larger number of max_iter in order for it to work. I did a GridSearch Cross Validation, the model is doing will with default value. Compare to three different datasets. The full dataset performed the best in terms of predicting the correct disposition, it's has both high Accuracy score and High AUC Score.

For GradientBoosting, I use most the default value as well. However, I did try to tun the best learning rate. With three different datasets. Only the Full dataset had the different learning rate. Also, from the result. The Full dataset performed the best in terms of predicting the correct disposition.

Both two models are all work well with he prediction, however, GradientBoosting is performing a little bit better with higher Accuracy score and AUC score.

In Conclusion:

To be able to predict correctly, we can't just use partial information to do the determination. We need to include all the Triage and Historical information from the patient in order to predict correctly. The features are important for the machine to learn.
